1. Linear fit. Fit the following data with uncertainties to a straight line:

a) Calculate the  $n \times m$  design matrix  $X = [x^0 \ x^1]$  for the linear fit y = f(x) = a + bx for n = 4 data points to m = 2 fit parameters, and write out the corresponding matrix equation Y = Xa. Calculate the weight [metric]  $W = \delta^{-2}Y$ , (inverse covariance matrix), the least squares inverse  $X^{-1} = (X^T W X)^{-1} X^T W$ , the fit coefficients  $a = X^{-1}Y$ , and covariance matrix  $\delta^2 a$ . Tabulate the residuals  $\chi = Y - Xa$ , individual squares  $\chi_i^2 = ((y_i - f(x_i))/\delta y_i)^2$ , and the sum  $\chi^2 = \chi^T W \chi$ . How many degrees of freedom  $\nu$  are there?

**b)** [bonus: Neglecting the uncertainties for simplicity, solve for  $X^{\dashv}$  by computing the Singular Value Decomposition (SVD)  $X = UWV^T$  of the  $n \times m$  matrix X, where U and V are orthogonal matrices of the singular vectors  $U^TU = I_n$ ,  $V^TV = I_m$ , and W is the  $m \times n$  diagonal matrix of singular values (eigenvalues) of X. Show algebraically that  $X^{\dashv} = VW^{\dashv}U^T$ , where  $W^{\dashv}$  is the  $m \times n$  diagonal matrix of inverse singular values. What is the geometric interpretation of the left and right singular vectors? Repeat with  $\delta^2 Y$  using the Generalized SVD. ]

2. The following waveform data in mV were captured on an oscilloscope with a  $\Delta t = 1$  ms sample interval, from the voltage output of a magnetometer measuring the field of an AC-driven coil:

V= [3.81, 2.96, 2.36, 2.40, 0.47, 2.29, 0.51, -0.06, -2.00, -0.42, 0.06, ...

0.57, 0.29, 2.07, 2.47, 2.86, 2.78, 1.86, 1.37, -0.43, 0.03]

Fit these data for the amplitude A, angular frequency  $\omega$ , phase  $\phi$ , and offset B of a sine wave in the semilinear model  $V(t) = A \cos(\omega t - \phi) + B$  ignoring errors using the following steps:

a) Plot the data and fit function, estimating of all four parameters (Note the data span approximately one period, ranging from the peak  $V \approx 2$  mV, to the minimum  $V \approx 0$  ms and back to the top). [bonus: estimate  $A, \phi, \omega$ , and B from the complex FFT of V.]

**b)** Linearize this model to  $V = B + C \cos(\omega t) + D \sin(\omega t) = Ta$  for constant  $\omega$  using the addition formula  $\cos(\alpha - \beta) = \cos(\alpha) \cos(\beta) + \sin(\alpha) \sin(\beta)$ . Follow the steps in 1a) to perform a linear fit on  $V \approx Ta$  for parameters  $a = (BCD)^T = T^{\dashv}V$ , and calculate  $\chi^2 = (V - Ta)^T (V - Ta)$ .

c) Fit for  $\omega$  by minimizing  $\chi^2$  as a function of  $\omega$ . [bonus: fit  $\chi^2(\omega)$  to a parabola] Calculate the fitted fitted amplitude, phase, and offset from the corresponding fit parameters a and plot V(t). Estimate the uncertainty  $\delta V$  of the voltage data by setting  $\chi^2 = \nu = 21 - 4$  the number of degrees of freedom. [bonus: find covariance matrix of the fit parameters from  $\delta^2 a$ .]

c) [bonus: Fit a histogram of the residuals to the Gaussian  $p_G(x) = N \exp(-((x - \mu)/\sigma)^2/2)$  by linearizing it to the quadratic form  $\ln(p_G) = a + bx + cx^2$  and performing a linear fit on the binned  $\chi^2$  data for  $(a \ b \ c)^T$ . Compare your fitted values of  $\mu$  and  $\sigma$  with the mean and residual of the distribution. Are they within error of what you expect, given  $\chi^2$  above? What is the likelihood of  $\chi^2$  being greater than the fitted value?
